## ABSTRACT OF THE DISCLOSURE

A wraparound delay amount detecting part calculates a cross-correlation r(k) from an output speech signal " $a_i$ " supplied to a loudspeaker and an input speech signal " $b_i$ " inputted through a microphone array to obtain a delay amount "d" of a wraparound speech signal. The delay processing part generates a speech signal " $a_{i \cdot d}$ " obtained by delaying the output speech signal " $a_i$ " by the delay amount "d". Even if there is a change in delay amount due to the variation in environment, appropriate delay processing can be conducted by the delay processing part. In an adaptive filter, an estimated wraparound speech signal  $a_{i \cdot d}$  is generated from the speech signal " $a_{i \cdot d}$ " subjected to delay processing. A subtracter subtracts the estimated wraparound speech signal  $a_{i \cdot d}$  from the input speech signal " $b_i$ " to generate an echo cancellation signal " $e_i$ ". A coefficient updating part updates the coefficient of the adaptive filter.
